Abstract. We apply systematic methods previously used by Mihalkovič *et al.* to predict the structure of the ‘basic’ Co-rich modification of the decagonal Al₇₀Co₂₀Ni₁₀ layered quasicrystal, based on known lattice constants and previously calculated pair potentials. The modelling is based on Penrose tile decoration and uses Monte Carlo annealing to discover the dominant motifs, which are converted into rules for another level of description. The result is a network of edge-sharing large decagons on a binary tiling of edge 10.5 Å. A detailed analysis is given of the instability of a four-layer structure towards *c*-doubling and puckering of the atoms out of the layers, which is applied to explain the (pentagonal) orientational order.

1. Introduction

A fundamental problem of theoretical solid-state chemistry is, *assuming* the ability to compute perfectly the total energy of a complex compound, to discover which arrangement of the atoms minimizes that energy. Quasicrystals offer a wonderful opportunity to face this problem, as many different arrangements are low in energy, but this approximate degeneracy is resolved by more subtle interactions, often in several steps of a hierarchy of length scales.

Consider decagonal Al-Co-Ni, the pre-eminent decagonal Al-TM quasicrystal (TM= transition metal), a phase which is divided into many modifications [1], of which the simplest are ‘basic’ Ni-rich (around Al₇₀Co₁₀Ni₂₀) and ‘basic’ Co-rich (around Al₇₀Co₂₀Ni₁₀). Mihalkovič *et al* [2] proposed a general method to discover the ground-state structure, taking as inputs the interatomic pair potentials, derived by Moriarty and Widom [3] using ‘generalized pseudopotential theory’, and the experimentally determined lattice constants. One initially describes the quasicrystal by a Penrose tiling of edge $a_0 \approx 2.45$ Å with properly placed candidate sites on the tiles. Monte Carlo annealing, in which atoms hop on these sites, is used to find low-energy configurations. (This approach was used earlier by Cockayne and Widom [4]

for decagonal Al-Co; Mihalkovič *et al* [2] added tile rearrangements as a helpful Monte Carlo move.). In the next stage, motifs abstracted from these results are converted into *rules* to decorate larger tiles, thereby reducing the degrees of freedom and permitting larger simulation cells in which further orderings can be seen.

2. Structure motifs and idealized decoration

We have applied this method to the ‘basic’ Co-rich composition (more complete accounts may be found in Refs. [5, 6].) From the initial stage simulation it became clear that the dominant motif is a decagon with edge $\tau a_0 \approx 4\text{\AA}$ and hence diameter $2\tau^2 a_0 \approx 12.8\text{\AA}$; in the rest of this paper, the term ‘13 Å Decagon’ refers exclusively to this object. The exact occupancies (fig. 1a) were clarified in the second stage of simulations. These were based on τa_0 -edge rhombi in arrangements favoured the densest possible packing of non-overlapping 13Å decagons made from the rhombi. (Overlaps were verified to be unfavourable energetically.) The atoms in a cluster are grouped into concentric rings (see figure 1a). Just inside the perimeter, a few Al sites form a partial ‘ring 2.5’ with elusively context-dependent occupancies. (The Al positions on each 13Å Decagon edge (ring 3) also may depend on the 13Å Decagon’s environment.) Almost all the TM atoms in the 13Å Decagon are Co, which is presumably why it emerges at higher Co content. (This was also discovered by Hiramatsu and Ishii [7], who did an exploratory study using the same code of a wider range of AlCoNi compositions.)

The best arrangements for edge sharing of the 13Å Decagons amounts to a 10.5 Å edge ‘binary tiling’ [8, 9], with the 13Å Decagons sitting on the Large-atom sites of the binary tiling. Filling the space between is a secondary motif, which is centred on the Small-atom sites, which we call the ‘Star cluster’ and show in figure 1(b). The centre of this cluster has a pentagon of five candidate TM sites, which are variably occupied by TM (almost always Ni) or Al.

The TM occupancies show context dependence, which we will approximate with a very simple rule (figure 1c). We have four classes of TM atom. On each of the binary tiling’s Large vertices we have a 13Å Decagon with five Co(1) in its centre and ten TM(3) on its perimeter (ring 3). (For visual clarity, the TM(3) are not shown in figure 1c.) Now, on each (binary-tiling) edge connecting a 13Å Decagon to a Star cluster centre, a Star cluster TM is strongly favoured or disfavoured according to whether the 13Å Decagon’s first ring has Al or TM on the same edge. (The distance between these sites is $5^{1/2}a_0 \approx 5.6\text{\AA}$, which is a maximum of $V_{\text{TM-TM}}(r)$ [3].) So, on *every* binary-tiling rhombus exactly half the edges do not pass over a Co(1): let us place on each such edge a Ni(*s*) within the Star cluster, and make the TM(3) site a Ni(3); all other TM(3) become Co(3). (As in the ‘basic’ Ni-rich composition, the difference between Ni and Co potentials favours Ni occupancy in TM-TM pairs and Co in lone TM sites.)

Finally, as this too is energetically favoured, we place 2 Ni(*s*′) wherever two Star clusters overlap, that is once on each Thin rhombus of the binary tiling. In a decagonal tiling, there is an average of 3.19 Ni on each Star cluster and the composition is $\text{Al}_{70}\text{Co}_{21.2}\text{Ni}_{8.8}$ (assuming the TM fraction is 30%). (One other

Figure 1. Decoration model (a). Decoration of a $13\text{\AA}$ Decagon, named in concentric rings. Size of circles indicates which of the two layers; some third-ring ‘Co’ atoms become Ni (as shown) but not many. Dashed ovals mark four (out of eight) of the places showing Co-Al-Al-Co in projection, which after relaxation become a channel like figure 2a. (b). Decoration of Star cluster. There are additional Al along the outer edges. (c). $13\text{\AA}$ Decagons and Star clusters shown with dashed edges, placed on vertices of the binary-tiling rhombi (edge $\tau^2 a_0 \approx 10.5\text{\AA}$). Filled circles are TM atoms in $13\text{\AA}$ Decagon and Star cluster interior. The $\pm$ sign on each $13\text{\AA}$ Decagon indicates $\sigma_i = \pm 1$. Ni(3) sites are shown in grey; there are Co atoms (not shown) on all other corners of the $13\text{\AA}$ Decagons.

version of the idealization, including the placement of Al atoms, is described by Gu *et al* [6], and gave a composition $\text{Al}_{70.1}\text{Co}_{22.4}\text{Ni}_{7.5}$, and it is even easier to devise variants with higher Ni content.)

This model does not include the ‘pentagonal bipyramid’ motif that is prominent in the related approximant $\text{W}(\text{Al-Co-Ni})$ [10], so we have not addressed whether that motif is favoured in the decagonal Al-Co-Ni structure [11].

3. Orientational order and puckering

A full structure description must specify, in each $13\text{\AA}$ Decagon’s first ring, the orientation of the pentagon formed by its ring 1 TM atoms (this is prominent in electron microscope images). Each orientation is parametrized by a spin-like variable $\sigma = \pm 1$, with $\sigma = +1$ when the Co_5 pentagon (projected on the xy plane) points up, that is when the five Co lie in the even-numbered atom layers. We seek an *effective interaction* of neighboring $13\text{\AA}$ Decagon’s, like the spin interaction in an Ising model. A cluster arrangement with all clusters oriented the same will be called ‘ferromagnetic’; that quasicrystal has global *pentagonal* (not decagonal) symmetry, as is observed in fact for one of the Co-rich modifications [12, 13].

3.1. Fixed site list: interaction via Star clusters

When we simulate with a fixed site list, there are small energy differences that favour either the ‘ferromagnetic’ or ‘antiferromagnetic’ order of $13\text{\AA}$ Decagon orientations, depending on the atom density assumed and which approximant is studied, showing there are competing contributions to the cluster-cluster effective interaction. (The

‘ferromagnetic’ effect wins for $0.068 - 0.074 \text{ \AA}^{-3}$, which includes the physically more reasonable densities.)

Where does the interaction come from? The only atoms that change with a cluster’s orientation are the central Al and the ring 1 Al_5Co_5 , but those are too distant to interact *directly*. (Our potentials were cut off around $7 \text{ \AA}$.) An *indirect* interaction may be mediated by other atoms in two ways. Firstly, the variable Al atoms in rings 2.5 and 3 are within range of ring 1 of both clusters; this guides whether the ring 3 Al (in projection) divide the $13 \text{ \AA}$ Decagon edge in the ratio $\tau^{-1} : \tau^{-2}$ or $\tau^{-2} : \tau^{-1}$ (See figure 1a.) This contribution favours ‘ferromagnetic’ order, so the shared $13 \text{ \AA}$ Decagon edges will match. (Expressed in energy terms, the argument is related to the one for the ‘puckering’ case in Sec. 4, below.)

Alternatively, neighboring TM atoms in the Star clusters interact with each other and also respond to the first-ring orientations of adjoining $13 \text{ \AA}$ Decagons: we suggest this is the origin of the ‘antiferromagnetic’ coupling, based on the TM rules of Sec. 2. Let us assume a repulsive energy V_{72} for Ni-Ni pairs on edges differing by 72° as found by Mihalkovič *et al* [2] in ‘basic’ Ni modification. One such pair appears on each Fat rhombus having $13 \text{ \AA}$ Decagons with the same orientation. The effective orientation interaction is then $\frac{1}{2}(1 + \sigma_1\sigma_2)V_{72}$ favouring the ‘antiferromagnetic’ arrangement. Thus, the two indirect effects are indeed competing.

4. Relaxation and puckering

Relaxation and molecular dynamics of the structures found in the fixed-site simulation were used to explore subtler aspects corresponding to small energy differences – including the relative orientation of neighboring clusters, which is a major focus of this paper. The most striking effect of letting atoms off of the fixed sites was that Al atoms in ring 2.5/ring 3 tended to run to new locations, in which they displaced from the layers in the z direction (puckering of atom layer). When we used a simulation cell with four layers, pattern of puckering is such that lattice constant doubled to $2c \approx 8 \text{ \AA}$. (That is the observed period of most Co-rich decagonal Al-Co-Ni modifications and approximants, and it was long known crystallographically that puckerings are the major way in which the real cells are doubled.)

4.1. Channels

How shall we best understand the positions taken by Al after they are freed from the fixed site list? Let us consider the net potential felt by an Al given the TM atoms, which we fix on ideal sites (they hardly displace under relaxation in any case). Winding one-dimensional ‘channels’ are found along which the potential is low and comparatively flat, typically between two columns of Co atoms (a ubiquitous pattern in the structure) forming a zigzag ladder, as shown in figure 2a. (Henley *et al* [14] discovered similar channels in ‘basic’ Ni-rich modifications from the time-averaged Al density in a molecular dynamics simulation.)

Figure 2. ‘Channels’ accommodating three Al atoms per four layers. (a). Path of a channel favourable to Al between two staggered columns of Co atoms; positions of the rigid site list shown as dashed circles. The farther TMs (grey) actually lie in a direction nearly normal to the paper. (b). Single-Al potential $U(z)$ in the channel, showing minimum-energy configuration of three atoms with period $2c$. (c). Four channels adjacent to single Co column; the two channels in the plane normal to the paper break the period c symmetry in the opposite way from the other two.

The single-Al potential in a channel may be approximated as

$$U(z) = U_0 - \tilde{U}_{c/2} \cos\left(\frac{4\pi z}{c}\right) + \sigma \tilde{U}_c \cos\left(\frac{2\pi z}{c}\right) \quad (1)$$

Using our potentials, $\tilde{U}_c \approx \tilde{U}_{c/2} \approx 0.2 \text{ eV}$ is found. Let us explain the origin of these coefficients. The Co atoms *adjacent* to the channel have symmetry under one-layer shifts, which explains the period- $c/2$ term of (1). Its minimum occurs in each atom layer, where the Al atom would be equidistant from three Co atoms at $r \approx 2.5 \text{ \AA}$, the minimum of the $V_{\text{AlCo}}(r)$ pair potential.

Figure 2 shows another column of TM farther away which breaks the degeneracy between even and odd layers. This explains the period- c term in equation (1), in which σ is the ‘spin’ variable defined above, and $\sigma = +1$ (resp. -1) when the distant Co atoms are in even (or odd respectively) layers. (The deeper minima occur in the TM-poor layer.) Note that U_c is proportional to $-dV_{\text{AlTM}}(r)/dr$, which happens to have a maximum at $r \approx 4 \text{ \AA}$, the distance to the distant column.

4.2. Puckering

Now, *three* Al atoms can and do fit into every four layers: their mean separation $2c/3 \approx 2.7 \text{ \AA}$ is right at the Al-Al hardcore radius. Just where do they prefer to lie in each channel? The optimum configuration has a symmetry such that $z_{3m} = m(2c)$, $z_{3m \pm 1} = z_{3m} \pm (2c/3 + u)$, [so the puckering displacement from a layer is $c/6 + u$; here m is any integer.] The total energy (per Al) is

$$E \equiv \frac{1}{3} \sum_{m=-1}^{+1} [U(z_m) + V(z_{m+1} - z_m)], \quad (2)$$

where $V(z' - z'')$ is the Al interaction along the channel. [Note a small abuse in this approximation: since the channels are not straight, the actual Al-Al distance is not

just a function of z [6]. Inserting z_m into equation (2) and Taylor expanding in u , we obtain

$$E = E_0 + \frac{2}{3}U_1' u + \left(V_1'' + \frac{1}{3}U_1'' \right) u^2. \quad (3)$$

Here $E_0 \equiv U_0 + V(2c/3)$. Also, $U_1' \equiv U'(2c/3)$, etc; inserting their values from equation (1), minimizing with respect to u , and using $U_1'' \ll V_1''$, we find the energy minimum

$$E_{\min} = E_0 - \left(\frac{\pi}{c} \right)^2 \frac{(2U_{c/2} + \sigma U_c)^2}{3V_1''}. \quad (4)$$

It can be seen this solution is favourable when $\sigma > 0$; that is, the *local* mirror layer of the Al's in each channel lies in the TM-rich layer [as observed in real Al-TM structures.] Then, when two (equi)distant TM columns affect the channel, $\sigma \rightarrow \sigma_1 + \sigma_2$ in equation (4) and the lowest $E_{\min}$ is obtained when $|\sigma_1 + \sigma_2| = 2$. Thus the relaxed total energy of channel Al favours a 'ferromagnetic' alignment of orientations, as was claimed.

Each channel breaks z -translation symmetry in that the mirror-layer Al sits at either $z = 0$ or $z = c$, but not both. These channels interact, in a pattern [6] whereby *four* channels get occupied around a single TM column, as shown schematically in figure 2c; viewed in projection, the mirror-layer Al atoms involved in the channels form a sort of bent cross.

(*Note added.* The puckering instability is presumably related to some very low frequency phonon modes [15]; the channels are also the conduit for the strong Al diffusion [16].)

5. Conclusion

To summarize, the methods developed by Mihalkovič *et al* [2] in a study of the 'basic' Ni-rich decagonal $\text{Al}_{70}\text{Co}_{10}\text{Ni}_{20}$ quasicrystal has successfully led to a structural understanding (at $T = 0$) of 'basic' Co-rich decagonal $\text{Al}_{70}\text{Co}_{20}\text{Ni}_{10}$, which is described by a completely different tiling, despite a very similar nearest-neighbor order. In this case, the key motif is a $12.6\text{\AA}$ diameter decagon having a pentagonal core.

We applied our approach to a unit cell the same size as $\text{W}(\text{Al-Co-Ni})$, a crystalline approximant of 'basic Co'. Many details of our prediction (most importantly the $13\text{\AA}$ Decagons, and the locations of their centres) are in agreement with the experimentally solved structure [17]. However, $\text{W}(\text{Al-Co-Ni})$ has a few highly puckered sites which can not be captured in our approach which begins using a fixed-site list and relaxes afterwards. [Mihalkovič and Widom [10] have given a more thorough ab-initio investigation of $\text{W}(\text{Al-Co-Ni})$.]

In general, the simulations with a fixed-site list – followed blindly – would lead to an imperfect description of Al atoms in ring 2.5 and ring 3 of the $13\text{\AA}$ Decagon. In simulations with relaxations (and in reality), many of these atoms displace from the layers, in a fashion which we have explained on the basis of the pair potentials.
